SCOPE

DISEASE/CONDITION(S)

Congestive heart failure

GUIDELINE CATEGORY

Diagnosis
Evaluation

CLINICAL SPECIALTY

Cardiology
Internal Medicine

Pulmonary Medicine
Radiology

INTENDED USERS

Physicians

GUIDELINE OBJECTIVE(S)

To provide appropriate recommendations for the use of chest radiography for the evaluation of patients with known or suspected congestive heart failure

TARGET POPULATION

Patients with known or suspected congestive heart failure

INTERVENTIONS AND PRACTICES CONSIDERED

Diagnosis/Evaluation

1. Chest radiography
2. Computed tomography (CT)
3. Magnetic resonance imaging (MRI)

MAJOR OUTCOMES CONSIDERED

Diagnostic utility (i.e., sensitivity, specificity) of chest radiography, computed tomography, and magnetic resonance imaging exam procedures

METHODOLOGY

METHODS USED TO COLLECT/SELECT EVIDENCE

Searches of Electronic Databases

DESCRIPTION OF METHODS USED TO COLLECT/SELECT THE EVIDENCE

The guideline developer performed literature searches of recent peer-reviewed medical journals, primarily using the National Library of Medicine's MEDLINE database. The developer identified and collected the major applicable articles.

NUMBER OF SOURCE DOCUMENTS

The total number of source documents identified as the result of the literature search is not known.

METHODS USED TO ASSESS THE QUALITY AND STRENGTH OF THE EVIDENCE

Weighting According to a Rating Scheme (Scheme Not Given)

RATING SCHEME FOR THE STRENGTH OF THE EVIDENCE

Not stated

METHODS USED TO ANALYZE THE EVIDENCE

Systematic Review with Evidence Tables

DESCRIPTION OF THE METHODS USED TO ANALYZE THE EVIDENCE

One or two topic leaders within a panel assume the responsibility of developing an evidence table for each clinical condition, based on analysis of the current literature. These tables serve as a basis for developing a narrative specific to each clinical condition.

METHODS USED TO FORMULATE THE RECOMMENDATIONS

Expert Consensus (Delphi)

DESCRIPTION OF METHODS USED TO FORMULATE THE RECOMMENDATIONS

Since data available from existing scientific studies are usually insufficient for meta-analysis, broad-based consensus techniques are needed to reach agreement in the formulation of the Appropriateness Criteria. Serial surveys are conducted by distributing questionnaires to consolidate expert opinions within each panel. These questionnaires are distributed to the participants along with the evidence table and narrative as developed by the topic leader(s). Questionnaires are completed by the participants in their own professional setting without influence of the other members. Voting is conducted using a scoring system from 1-9, indicating the most to the least appropriate imaging examination or therapeutic procedure. The survey results are collected, tabulated in anonymous fashion, and redistributed after each round. A maximum of three rounds is conducted and opinions are unified to the highest degree possible. Eighty (80) percent agreement is considered a consensus. If consensus cannot be reached by this method, the panel is convened and group consensus techniques are utilized. The strengths and weaknesses of each test or procedure are discussed and consensus reached whenever possible.

RATING SCHEME FOR THE STRENGTH OF THE RECOMMENDATIONS

Not applicable

COST ANALYSIS

A formal cost analysis was not performed and published cost analyses were not reviewed.

METHOD OF GUIDELINE VALIDATION

Internal Peer Review

DESCRIPTION OF METHOD OF GUIDELINE VALIDATION

Criteria developed by the Expert Panels are reviewed by the American College of Radiology (ACR) Task Force on Appropriateness Criteria and the Chair of the ACR Board of Chancellors.

<div style="background-color:teal; color:white; text-align:center;">RECOMMENDATIONS</div>

MAJOR RECOMMENDATIONS

ACR Appropriateness Criteria™

Clinical Condition: Congestive Heart Failure (CHF)

Variant 1: New CHF, suspected based on symptoms and physical examination

Radiologic Exam Procedure	Appropriateness Rating	Comments
Chest radiograph	9	
Computed tomography (CT)	2	CHF is readily diagnosed on CT obtained for other indications.
Magnetic resonance imaging (MRI)	2	
Appropriateness Criteria Scale		
1 2 3 4 5 6 7 8 9		
1=Least appropriate 9=Most appropriate		

Variant 2: Previous CHF, currently stable

Radiologic Exam Procedure	Appropriateness Rating	Comments
Chest radiograph	4	
CT	2	CHF is readily diagnosed on CT obtained for other indications.
MRI	2	
Appropriateness Criteria Scale		
1 2 3 4 5 6 7 8 9		
1=Least appropriate 9=Most appropriate		

Variant 3: Previous CHF, new-onset signs and symptoms

Radiologic Exam Procedure	Appropriateness Rating	Comments
Chest radiograph	9	
CT	2	CHF is readily diagnosed on CT obtained for other indications.
MRI	2	
Appropriateness Criteria Scale 1 2 3 4 5 6 7 8 9 1=Least appropriate 9=Most appropriate		

A variety of definitions exist as to what constitutes congestive heart failure (CHF). An accepted physiologic definition is the failure of the heart to pump sufficient blood to supply the needs of the metabolizing tissues. Either systolic or diastolic dysfunction can lead to CHF. Congestive heart failure is most commonly due to ischemic heart disease. Other causes include valvular heart disease, cardiomyopathies, hypertension, and left-to-right shunts. Clinically, heart failure is recognized by occurrence of signs and symptoms of heart failure in combination with objective evidence of cardiac dysfunction. Signs and symptoms of heart failure include dyspnea on exertion or orthopnea, elevation of the jugular venous pressure, and pitting edema of the ankles. A third heart sound is often heard but this finding is subject to substantial interobserver variability. Objective methods of evaluating cardiac function include chest radiography, nuclear cardiology, echocardiography, cardiac catheterization, computed tomography (CT) scanning or magnetic resonance imaging (MRI), electrocardiography, and exercise testing. The guidelines deal predominately with the usefulness of the chest radiograph for the evaluation of patients with known or suspected CHF. It is important to note that patients with diseases other than CHF may have one or several of the signs and symptoms of CHF.

Chest Radiography

The chest radiograph is a useful technique to screen patients who exhibit the signs and symptoms of CHF. Several typical findings of CHF occur in patients who undergo radiography in an erect position. At an early stage, the normally gravity-dependent blood flow may become equalized, with upper and lower lung vessels of similar caliber. Later, upward diversion of blood flow may be present such that the upper lobe vessels are larger than those in the lower lungs.

If pulmonary wedge pressure is higher, Kerley A and B lines, which consist of thickened edematous interlobular septa, may become evident. Kerley A lines are lengthy and radiate from the hilum. Kerley B lines are best visualized oriented perpendicularly to the lateral pleural margin above the costophrenic angles. Peribronchial cuffing and blurring of vessels may occur because of fluid infiltration adjacent to these structures. At the highest pulmonary wedge pressure, flooding of alveoli causes airspace edema.

Several studies have assessed the relationship between findings of pulmonary venous hypertension and measures of left ventricular function. Madsen et al assessed the value of chest radiography to predict abnormal left ventricular

function following acute myocardial infarction. The sensitivity of radiographic pulmonary venous congestion for depressed ejection fraction was 52%; specificity was 74%. Herman et al evaluated 104 patients with varying degrees of left ventricular dysfunction. They reported that while most patients with elevated left ventricular end diastolic pressure had radiographic evidence of CHF, 38% did not. Baumstark et al, Costanzo et al, and Balbarini et al have all reported a significant but imperfect correlation between radiographic findings of pulmonary venous hypertension and left ventricular dysfunction.

The cardiac silhouette is variably enlarged in CHF. The size of the heart has only a weak, clinically insignificant correlation with severity of CHF as measured by ejection fraction. Patients with an initial myocardial infarction who have severe cardiac dysfunction may have a nearly normal cardiac size because the heart may not dilate acutely. Dash et al investigated 82 patients with CHF and found that the cardiothoracic ratio correlated best ($r = 0.70$) with the degree of elevation of capillary wedge pressure. In the study of Madsen et al, enlargement of cardiothoracic ratio (threshold = 0.5) had a sensitivity of 47% for detecting an abnormal ejection fraction (≥ 0.51). Philbin et al assessed the utility of cardiothoracic ratio to estimate ejection fraction in 7,476 patients with left-sided heart failure and found only a limited correlation ($r = 0.18$).

An enlarged vascular pedicle is also often present in CHF. The vascular pedicle is defined as the sum of the distance of the right mediastinum at the level of the azygos arch to the midline and base of left subclavian artery to midline. This method of evaluating fluid status has been advocated by Milne et al and Pistolesi et al. It does thus reflect fluid status in both the arterial and venous system. However, variability in mediastinal widths between patients mitigates some advantages of this technique. In practice, the use of the vascular pedicle is best applied to assessment of volume status of an individual patient, provided changes in patient positioning, depth of inspiration, and tube position are taken into account. Pleural effusions are common in patients with CHF. Other radiographic findings that may aid in the diagnosis of CHF are a relative increase in pulmonary artery–bronchus ratio in the upper as compared with lower lung zones and thickening of the posterior wall of the bronchus intermedius on the lateral radiograph.

In patients who are unable to cooperate for an erect posteroanterior and lateral radiograph, particularly those in the intensive care unit (ICU), portable radiography may be necessary. Portable radiography is most often obtained with the patient in a semi-erect or supine position, which alters the appearance of radiographic findings of CHF. In a supine position, equalization of vasculature or flow inversion is physiologically normal. Thus, recognition of CHF depends to a greater extent on the presence of pulmonary edema, which occurs only in more severe cases. In the ICU, airspace edema caused by CHF is often difficult to distinguish from non-cardiogenic edema and diffuse pulmonary infection.

Pleural effusions are also more difficult to recognize in the recumbent patient. Free pleural effusions layer in the posterior pleural cavity, creating a homogeneous opacity that may show a gradient of opacity from a caudal to cephalic direction, depending on the degree of patient recumbency. Bronchovascular markings are often visible through the hazy opacity. The presence of effusion can be confirmed by obtaining a lateral decubitus view.

The chest radiograph may occasionally show an atypical pattern in CHF. The best-characterized situation is in patients who develop acute mitral regurgitation, in which a strikingly asymmetric edema pattern occurs with predominant opacity in the right upper lobe. This pattern is caused by the flow vector in mitral regurgitation, which is usually directed toward the right superior pulmonary vein. In patients who have chronic lung disease due to parenchymal fibrosis or emphysema, the appearance of CHF can be atypical. With emphysema, the chest radiograph may show an accentuation of preexisting interstitial lines rather than airspace edema because of alveolar destruction in emphysematous areas.

The chest radiograph is also useful for diagnosing diseases other than CHF in patients with dyspnea. The radiographic distinction of CHF from increased permeability edema, of which the adult respiratory distress syndrome is the prototype, may be difficult. Findings that favor CHF are an enlarged cardiac silhouette, Kerley lines, and pleural effusions. Lobar pneumonia and abscess, pulmonary infarction, lung masses or nodules and focal pleural disease are usually readily distinguishable from CHF.

CT Scan

The role of CT scanning in patients with CHF is limited. However, CT scanning that is obtained for other indications may show evidence of CHF and thus recognition of findings in this entity is important. In CHF, animal studies have shown an increase in arterial and venous size and increased parenchymal opacification. In patients, gravity-dependent flow inversion causes enlargement of nondependent vessels (anterior vessels in supine patients). Interstitial edema produces thickening of interlobular septa and the peribronchovascular and subpleural interstitia. In patients with airspace edema, ground glass opacity is evident on standard and high-resolution CT. Pleural and pericardial effusions are more apparent and are easier to quantify on CT than on chest radiography.

MRI

Magnetic resonance imaging provides a large quantity of morphologic and physiologic information in the evaluation of the heart. Wall thickness and cavity size are easily measured. Cine MRI permits assessment of cardiac function and wall motion abnormalities. Active investigation is being undertaken in the areas of myocardial perfusion imaging and coronary artery assessment. Despite its considerable promise, MRI has yet to be widely adopted in clinical practice.

Summary

The various studies on the utility of chest radiography for CHF draw conclusions that are inconsistent and even contradictory. Nevertheless, the preponderance of data shows that most patients with CHF have radiographic abnormalities that may suggest the diagnosis. Thus use of chest radiography as part of the initial assessment of patients with suspected heart failure seems appropriate. Similarly, in patients with known CHF whose clinical picture deteriorates from baseline, the data suggest that chest radiography is beneficial. Both CT and MRI may ultimately prove valuable to evaluate CHF, but should be regarded as investigational at the present time.

TYPE OF EVIDENCE SUPPORTING THE RECOMMENDATIONS

The recommendations are based on analysis of the current literature and expert panel consensus.

POTENTIAL BENEFITS

Appropriate use of chest radiography for the evaluation of patients with known or suspected congestive heart failure

POTENTIAL HARMS

Not stated

QUALIFYING STATEMENTS

An American College of Radiology (ACR) Task Force on Appropriateness Criteria and its expert panels have developed criteria for determining appropriate imaging examinations for diagnosis and treatment of specified medical condition(s). These criteria are intended to guide radiologists and referring physicians in making decisions regarding radiologic imaging and treatment. Generally, the complexity and severity of a patient's clinical condition should dictate the selection of appropriate imaging procedures or treatments. Only those exams generally used for evaluation of the patient's condition are ranked. Other imaging studies necessary to evaluate other coexistent diseases or other medical consequences of this condition are not considered in this document. The availability of equipment or personnel may influence the selection of appropriate imaging procedures or treatments. Imaging techniques classified as investigational by the United States Food and Drug Administration (FDA) have not been considered in developing these criteria; however, study of new equipment and applications should be encouraged. The ultimate decision regarding the appropriateness of any specific radiologic examination or treatment must be made by the referring physician and radiologist in light of all the circumstances presented in an individual examination.
